(Received 20 July 2007; accepted 22 October 2007; published online 6 December 2007)

The linear stability characteristics of pressure-driven two-layer channel flow are considered, wherein a Newtonian fluid layer overlies a layer of a Herschel-Bulkley fluid. A pair of coupled Orr-Sommerfeld eigenvalue equations are derived and solved using an efficient spectral collocation method for cases in which unyielded regions are absent. An asymptotic analysis is also carried out in the long-wave limit, the results of which are in excellent agreement with the numerical predictions. Our analytical and numerical results indicate that increasing the dimensionless yield stress, prior to the formation of unyielded plugs below the interface, is destabilizing. Increasing the shear-thinning tendency of the lower fluid is stabilizing. © 2007 American Institute of Physics.

[DOI: 10.1063/1.2814385]

I. INTRODUCTION

In several applications, layers of highly viscous fluids are displaced by another fluid. In the cleaning of fast-moving consumer good plants, for example, a highly viscous fluid is removed by pumping water through the plant. A common feature of the rheology of these fluids is the appearance of a yield stress. This concept has been challenged in several studies, but remains a very useful approximation (see Ref. 1 for an extensive review, and Ref. 2 for recent detailed measurements). In this paper, we study the stability of a fluid that exhibits a finite yield stress superposed by a Newtonian fluid, as shown in Fig. 1. A yield stress may affect the growth of interfacial waves, which ultimately would influence the rate at which the highly viscous layer is removed.

Some relevant key features of the linear stability of planar two-fluid Poiseuille flow are briefly reviewed here; an extensive review can be found in Ref. 3. The early work of Yih,4 who considered the stability of this flow to two-dimensional long-wave disturbances, elucidated the origin of the interfacial instability. Yih used an asymptotic analysis to derive an expression for the complex wave speed as a function of the relevant system parameters such as the density, viscosity, and thickness ratios. He then demonstrated that instability exists due to an interfacial mode which results from a viscosity stratification even in the limit of vanishingly small Reynolds numbers. Yiantsios and Higgins5 subsequently numerically showed the appearance of a shear mode at sufficiently large Reynolds numbers, which corresponds to a short-wave Tollmien-Schlichting mode.

Yiantsios and Higgins5 also carried out an asymptotic analysis and extended the work of Yih to cover large wave numbers and to account for the effects of gravity and interfacial tension using the perturbation scheme of Hooper and Boyd; the latter authors examined the short-wave asymptotics of the interfacial instability between two unbounded viscous fluids. They provided predictions of critical Reynolds numbers for both the shear and interfacial modes and demonstrated the existence of discrepancies between these predictions and the experimental data of Kao and Park.8 They also compared their results with the weakly nonlinear evolution of the interface considered by Hooper and Grimshaw.9

The stability of inelastic non-Newtonian fluids has been studied before (the extensive literature on the stability of elastic fluids, see, for instance, Refs. 10–15, is not reviewed here). Most relevant here is a previous study by Frigaard16 on the linear stability of two-layer Poiseuille flow of two Bingham fluids. In the flows considered there, the shear stress distribution is assumed to be such that only a fraction of the Bingham fluid has yielded. In the present configuration, this would amount to an unyielded region between the Newtonian fluid and the yielded part of the Bingham fluid, hence interfacial waves would not develop under such conditions. This suppression of interfacial modes then leads to superstable two-layer flows.16 The flow would be increasingly stable at larger values of the yield stress, similar to single-fluid pressure-driven flows17 (this was also noticed by Pinarbası and Liakopoulos18 but they used a regularized rheological model).

This previous work, however, does not address the stability of flows of a Newtonian fluid parallel to a Bingham fluid at flow rates sufficient for the entire Bingham fluid to yield (in a linear analysis), which would be appropriate for applications wherein the applied pressure gradient is simply too large. Also of practical relevance are situations in which fluids exhibit shear-thinning or shear-thickening behavior; this is commonly represented by so-called Herschel-Bulkley (HB) models, which incorporate the presence of a yield stress as well as power-law behavior. The linear stability of an interface separating a Newtonian and Herschel-Bulkley fluid in pressure-driven channel flow has only been partially studied previously, primarily using long-wave approximations, for power-law fluids. Khomami19,20 showed through an asymptotic analysis in this limit that a regularized power-law model with a low-shear-Newtonian plateau should be used, otherwise the predictions would be misleading at low thickness ratios. Pinarbası and Liakopoulos18 also solved the Orr-
II. FORMULATION

A. Governing equations

We consider the two-dimensional flow of two-fluids in a channel driven by a constant pressure gradient in the streamwise direction. The upper and lower fluids are assumed to be Newtonian and non-Newtonian, respectively; both fluids are incompressible. We use a rectangular coordinate system to analyze the linear stability characteristics of this flow; x and y denote the streamwise and wall normal directions, respectively, as indicated in Fig. 1. The direction of the gravitational acceleration is assumed to be aligned with the y-axis. The lower and upper channel walls are located at y=0 and y=H, respectively, and the sharp interface, which separates the immiscible fluids, is at y=h.

We have adopted the Herschel-Bulkley model to describe the rheological characteristics of the non-Newtonian fluid,

\[ \mu_1 = k\Pi^{n-1} + \tau_0\Pi^{-1} \]

where \( \mu_1 \) is the apparent viscosity, \( k \) and \( n \) denote the consistency and flow index, and \( \tau_0 \) is the yield shear stress; \( \Pi = (2E_{ij}E_{ij})^{1/2} \) represents the second invariant of the rate of strain tensor, \( E_{ij} = \frac{1}{2}(\partial u_i/\partial x_j + \partial u_j/\partial x_i) \). As explained in the Introduction, we restrict the analysis to sufficiently low values of \( \tau_0 \) so that there are no unyielded regions in \( 0 \leq y \leq h \).

Solutions of the equations of motion are sought subject to the no-slip and no-penetration conditions at the walls, continuity of the normal and tangential components of the velocity and stress fields, and the kinematic condition at the interface. These equations and boundary conditions are rendered dimensionless using the velocity scale, \( V \), the channel height, \( H \), and the density and viscosity of the upper fluid, \( \rho_2 \) and \( \mu_2 \), respectively; they are not presented here for brevity. (The subscripts 1 and 2 are used to represent quantities associated with the lower and upper fluids, respectively.)

The reduced dimensionless pressure \( P_i \) in fluid \( i \) is related to the corresponding total dimensional pressure \( p_i \) through

\[ P_i = \frac{H}{\mu_2 V} \left[ p_i + \rho_2 g(y - h) \right] \quad (i = 1, 2), \]

where \( g \) is the gravitational acceleration. This effectively transfers the hydrostatic term from the momentum conservation equations to the interfacial normal stress boundary conditions, as will be shown below. The dimensionless viscosity of the non-Newtonian fluid is

\[ \mu_1 = m\Pi^{n-1} + Bn\Pi^{-1} \]

where \( Bn = \tau_0 H / \mu_2 V \) is a Bingham number and \( m = \mu_1^{-1}k(V/H)^{n-1} \) is a viscosity ratio.

The base state corresponds to a steady and unidirectional velocity field in both layers, driven by a linear pressure distribution in x \( (P_1 = P_2 = P) \), for a flat interface,

\[ U_1 = \frac{n}{n+1} \left( \frac{dP}{dx} \right)^{-1} \left( \frac{dP}{dx} + c_3 - Bn \right)^{n+1/n} + c_4, \]

where \( c_3 \) and \( c_4 \) are constants derived from the boundary conditions at the interface and the channel walls.

The results of the numerical solution and a long-wave asymptotic analysis of this Orr-Sommerfeld eigenvalue problem show that increasing the yield stress (prior to the formation of unyielded regions) and the shear-thickening tendency of the non-Newtonian fluid promote instability. The results presented here also provide an important benchmark for full numerical simulations of these flows, using, e.g., level-set or phase-field methods, for the study of the subsequent nonlinear evolution.
The pressure gradient, \( \frac{dP}{dx} \), and the integration constants, \( c_1, c_2, c_3, \) and \( c_4 \) are obtained by solving the following simultaneous equations:

\[
\frac{n(dP/dx)^{-1}}{(n+1)m^{1/n}} \left( \left( \frac{dP}{dx} h + c_3 - Bn \right)^{n+1/n} - (c_3 - Bn)^{n+1/n} \right) - \frac{1}{2} \frac{dP}{dx} (h^2 - 1) - c_1 (h - 1) = 0,
\]

\[
c_3 = c_1, \quad c_2 = - \frac{1}{2} \frac{dP}{dx} - c_1,
\]

\[
c_4 = - \frac{n(dP/dx)^{-1}}{(n+1)m^{1/n}} (c_3 - Bn)^{n+1/n},
\]

and

\[
\int_0^1 U_1 dy + \int_0^1 U_2 dy = 1.
\]

Equations (6) arise from imposing the no-slip conditions at the upper and lower walls and demanding continuity of velocity and stress at the interface, while Eq. (7) represents a condition of constant volumetric flow rate, \( Q = VH \).

In Fig. 1, it is seen that increasing the value of \( Bn \) leads to an increase in maximal velocity contrast between the upper and lower fluids. Our base state results also demonstrate (not shown) that decreasing (increasing) \( n \) below (above) unity, which corresponds to a shear-thinning (shear-thickening) fluid has the opposite effect. These features indicate that increasing \( n \) and \( Bn \) is expected to exert a destabilizing influence on the flow.

B. Linear stability analysis

We investigate the stability of the base state characterized by \( U_1 \) and \( U_2 \) to infinitesimal, two-dimensional (2D) disturbances using normal modes by expressing each flow variable as the sum of a base state and a 2D perturbation,

\[
(u, v, p)(x, y, t) = [U(y), 0, P] + (\hat{u}, \hat{v}, \hat{p})(x, y, t),
\]

with \( i = 1, 2 \). Similarly the viscosity, \( \mu_i \), and \( h \) can be expanded as follows:

\[
\mu_i(\pi) = \mu_i^0 + \frac{\partial \mu_i}{\partial \pi} (\pi - \Pi) \equiv \mu_i^0 + \beta_\pi \hat{\pi},
\]

\[
h(x, t) = h_0^i + \hat{h}(x, t),
\]

where \( \beta = (n-1)m^{-2} - Bn \Pi^{-2} \) and the superscript \( 0 \) designates base state quantities. Substitution of Eqs. (8) and (9) into the governing equations, subtraction of the base state equations, and subsequent linearization yields the equations that determine the linear stability of the flow cast in terms of primary variables. These equations are then re-expressed in terms of the stream function, \( (u_i, v_i) = (\partial \Psi_i / \partial x, -\partial \Psi_i / \partial y) \) \( i = 1, 2 \) and the decomposition \( \Psi(x, y, t) = \phi(y) e^{i(\alpha x - \omega t)} \) is imposed, whence,

\[
(\hat{u}_i, \hat{v}_i, \hat{p}_i, \hat{\pi})(x, y, t) = (\psi_i, -i \alpha \phi \psi_i, \pi_i)(y) e^{i(\alpha x - \omega t)}, \quad \hat{h}(x, t) = \eta e^{i(\alpha x - \omega t)}, \quad i = 1, 2.
\]

Here, \( \psi_i \) and \( \eta \) denote the amplitudes of the stream function and interfacial perturbation, respectively, \( \alpha \) is a streamwise (real) wavenumber, \( \omega(=\alpha \omega) \) is a complex frequency, \( c \) is a complex phase speed of the disturbance; the prime represents differentiation with respect to \( y \). Note that \( \omega_i > 0 \) indicates the presence of a linear instability.

Eliminating the pressure perturbations in the usual way, yields the following coupled Orr-Sommerfeld-type equations:

\[
\begin{align*}
\text{i} \alpha & \text{Re} [\{ \psi''_i - \alpha^2 \psi_i \} (U_1 - c) - \psi'_1 U''_1] \\
& = \mu''_i \psi''_i - 2 \alpha^2 \psi''_i + \alpha^4 \psi_i + \beta U''_1 \pi'' + 2 \beta U'_1 \pi' \\
& + \beta U''_1 \pi + \alpha^2 \beta U'_1 \pi - 2 \alpha^2 \mu''_i \psi_i + \mu''_i \psi''_i + 2 \mu''_i \psi'_i \\
& + 2 \beta U'_1 \pi + 2 \beta' U'_1 \pi + 2 \beta'' U'_1 \pi + \mu''_i \alpha^2 \psi_i,
\end{align*}
\]

\[
\begin{align*}
\text{i} \alpha & \text{Re} [\{ \psi''_2 - \alpha^2 \psi_2 \} (U_2 - c) - \psi'_2 U''_2] \\
& = \psi'''_2 - 2 \alpha^2 \psi'''_2 + \alpha^4 \psi_2,
\end{align*}
\]

where \( r = \rho_1 / \rho_2 \) is the density ratio and \( \text{Re} = \rho_2 VH / \mu_2 \) is the Reynolds number. In the limit \( (n, Bn) \to (1, 0) \), these equations reduce to those used to study the stability of a two-layer Newtonian system.

The eigenvalue \( c \) and the eigenfunctions \( \psi_1 \) and \( \psi_2 \) are obtained via solution of Eqs. (11) and (12) subject to the following boundary conditions: the no-slip and no-penetration conditions at the walls,

\[
\psi_1 = \psi_1' = 0, \quad \text{at } y = 0,
\]

\[
\psi_2 = \psi_2' = 0, \quad \text{at } y = 1;
\]

continuity of the velocity components and of the normal and tangential stress components, and the kinematic condition at the interface,

\[
\psi_1 = \psi_2,
\]

\[
\psi'_1 - \psi'_2 + \eta (U'_1 - U'_2) = 0,
\]

\[
\psi''_2 - \alpha^2 \psi_2 - \mu''_i (\psi''_1 - \alpha^2 \psi_1) = 0,
\]

\[
\alpha \text{Re} [\{ \psi''_1 (c - U_1) + \psi'_1 U''_1 - \alpha \text{Re} [\{ \psi''_2 (c - U_2) + \psi'_2 U''_2] \\
& + 2 \alpha^2 \mu''_i \psi_1' - \alpha^4 \psi_i + \mu''_i \psi''_i + 2 \mu''_i \psi'_i \\
& + \mu''_i (\psi''_2 + \alpha^2 \psi_2) + \beta U'_1 \pi' + \beta' U'_1 \pi + \beta'' U'_1 \pi - \psi''_2 \\
& - (\Gamma \alpha^2 + G) \alpha (\psi'_1 - \psi'_2) (U'_2 - U'_1) = 0,
\]

where \( \eta \) is readily determined to be

\[
\eta = \psi'_1 (c - U_1) = \psi'_2 (c - U_2).
\]

Here, \( G = (\rho_1 - \rho_2) g H^2 / \mu_2 V \) and \( \Gamma = \sigma / \mu_2 V \) represent a Bond number and an inverse capillary, respectively, in which case \( \sigma \) denotes the interfacial tension.
C. Numerical procedure and validation

Solutions of Eqs. (11) and (12) subject to boundary conditions (13)–(18) are obtained using the spectral collocation method. The eigenfunctions, ψ₁ and ψ₂ are expanded using Chebyshev polynomials in the intervals [0, h] and [h, 1], respectively. The eigenvalue problem is then recast into the following matrix form:

\[
\begin{bmatrix}
A_{11} & A_{12} \\
A_{21} & A_{22}
\end{bmatrix}
\begin{bmatrix}
\psi_1 \\
\psi_2
\end{bmatrix}
= c
\begin{bmatrix}
B_{11} & B_{12} \\
B_{21} & B_{22}
\end{bmatrix}
\begin{bmatrix}
\psi_1 \\
\psi_2
\end{bmatrix},
\]

(20)

and solved using the public domain software, LAPACK. A similar technique has previously been used to study the stability of flow through a pipe. This procedure allows the numerical calculation of dispersion relations ω₂ = ω₁(α; Bn, m, Re, r, Γ, G).

The dependence of our numerical solutions upon mesh refinement is investigated in Fig. 2, in which we plot ω₂ against α for Re=100, h=0.5, m=10, r=1.1, G=10, Γ=1, Bn=4, and n=1. It is seen that the curves for different values of the order of Chebyshev polynomials, N, are virtually indistinguishable for N≥61. The results discussed in the rest of this paper were generated using N=101.

In order to validate the predictions of our numerical procedure, we have also made detailed comparisons with several published results for single and two-layer Newtonian flows. In Fig. 3, we compare our results with those of South and Hooper [see Fig. 4(c) in Ref. 23] and find excellent agreement. Excellent agreement is also found with the work of Yiantsios and Higgins (not shown).

D. Asymptotic analysis: α→0, “long-wave” limit

Here, we consider perturbations whose wavelength far exceeds the channel height. Our aim is to extend previous analyses to account for the effects of finite yield stress with n=1 and to use these results as a further check on our numerical predictions; a similar analysis has previously been carried out for power-law fluids. We use a regular perturbation expansion in powers of α for ψ₁, ψ₂, η and the eigenvalue, c:

\[\psi_i, η, c \sim (ψ_0, η_0, c_0) + α(ψ_1, η_1, c_1) + O(α^2), \quad i = 1, 2.\]

(21)

Substitution of Eq. (21) into Eqs. (11) and (12), and Eqs. (13)–(18) yields a sequence of problems, which are solved order-by-order in powers of α.

The analysis is standard, and follows closely the procedure employed by Yiantsios and Higgins. At leading order, the eigenfunctions are given by

\[
\psi_{10} = A_{00} + A_{01}y + A_{02}y^2 + A_{03}y^3,
\]

\[
\psi_{20} = B_{00} + B_{01}y + B_{02}y^2 + y^3,
\]

(22)

and at O(α), the solutions read...
The coefficients $A_{ki}$ and $B_{kj}$ ($i = 0, \ldots, 3$, $j = 0, \ldots, 2$, $k = 0, 1$) are chosen such that Eqs. (13)–(18) are satisfied; we have set the coefficients of the terms proportional to $y^3$ in Eqs. (22) and (23) to unity without any loss of generality. The leading order and $O(\alpha)$ wave speeds, $c_0$ and $c_1$ are determined from Eq. (19).

We have found $c_0$ to be real and expressed by

$$c_0 = \frac{(dP/dx + 2Bn)(h^0 - 1)\beta_1(dP/dx) + 2(h^0 - 1)h^0mBn}{2[h^0(m - 1) - m][\beta_2(dP/dx) - 6(h^0 - 1)h^0mBn]}.$$  \hfill (24)$$

where $\beta_1$ and $\beta_2$ are given by

$$\beta_1 = [(a^0)^2(m - 1) - m][h^0(h^0 - 2)(m - 1) + m],$$

$$\beta_2 = (h^0)^2 - 2h^0(h^0 - 1)[2 + (h^0 - 1)h^0]m + m^2(h^0 - 1)^4.$$ \hfill (26)$$

Hence $c_0$ depends on $m$, $h^0$, $dP/dx$ as well as $Bn$, whereas the dependence on $Re$, $r$, and $G$ arises only at $O(\alpha)$. The expression obtained for $c_1$ as a function of system parameters is rather cumbersome and will not be reproduced here, but our $O(\alpha)$ analysis shows that $c_1$ is purely imaginary.

We conclude this section with a comparison of the results of the asymptotic analysis with the predictions of the numerical procedure. In Fig. 4, we show the numerical solution of the eigenvalue problem using the spectral collocation method and the predictions of the long-wave theory. Inspection of Fig. 4 reveals that excellent agreement is obtained in the limit of small $\alpha$ with deviations becoming apparent with increasing $\alpha$, as expected. This inspires further confidence in the predictions of our numerical procedure.

III. RESULTS

In this section, we provide a discussion of our numerical results. Particular attention will be given to the effect of varying $Bn$ and $n$ on the linear stability characteristics since the influence of $m$, $r$, $h^0$, $G$, and $\Gamma$ on the stability of two-layer flows has been well studied.

A. Interfacial” mode

We investigate first the effect of varying the Bingham number, $Bn$, on the linear stability characteristics. In Fig. 5, we plot numerically generated dispersion curves with $n = 1$, $Re = 100$, $m = 10$, $r = 1.1$, $G = 10$, and $\Gamma = 1$. The choice of these parameters is reflective of physical situations wherein a Newtonian layer flows past a more dense and viscous layer of a Bingham fluid. The dispersion curves depicted in Fig. 5 are paraboloidal, and $\omega_i > 0$ over a finite band of wavenumbers, indicating the presence of a linear instability; there are also well-defined “most-dangerous” and “cut-off” modes that correspond to the values of $\alpha$ for which $\omega_i$ is maximal and beyond which $\omega_i > 0$, respectively. As shown in Fig. 5(a), increasing $Bn$ for $h^0 = 0.5$ is destabilizing, leading to an increase in the value of the wavenumber associated with the cut-off mode and an increase in the maximal growth rate; the most dangerous mode wavenumber appears to be weakly dependent on $Bn$. For $h^0 = 0.2$, however, increasing $Bn$ increases the cut-off mode wavenumber but decreases the maximal growth rate; hence its overall effect is stabilizing.

The dotted line in Fig. 5 shows the dispersion curve determined by performing a linear stability analysis of the base state associated with $Bn = 12$ but by setting $Bn = 0$ in Eqs. (11) and (12). The aim of this analysis is to isolate the effects of having a finite yield stress on the linear stability of the two-layer flow through its modification of the base state. Inspection of Fig. 5 reveals that such an analysis provides a reasonable approximation for low to intermediate wavenumbers but underestimates the maximal growth rate and the cut-off wavenumber.

In order to identify the nature of unstable modes, we

perform an energy decomposition following the methodology outlined in the Appendix. The energy “budgets” associated with the points labelled A, B, and C in Fig. 5(a) at \( \alpha=6 \) for \( \hbar^0=0.5 \), \( Bn=0 \), \( Bn=5 \), and \( Bn=12 \), respectively, are given in Table I. Similarly, energy budgets for points D and E for \( \hbar^0=0.2 \), which correspond to \( \alpha=5.6 \), \( Bn=5 \), and \( Bn=8 \), respectively, are also provided in Table I. The figures in Table I represent the contribution arising from each term in Eq. (A1) scaled by the total spatially averaged rate of change of disturbance kinetic energy, KIN.

The energy decomposition reveals that, since TAN provides the largest positive contribution to KIN, the unstable modes examined are all of the “interfacial” type, and, in this case, are driven by viscosity as well as density stratification. The Reynolds stress in the upper fluid, REY2, is destabilizing.

FIG. 6. The effect of varying the flow index, \( n \), on the dispersion curves: (a) \( h^0=0.5 \) and (b) \( h^0=0.2 \). Here, \( Bn=4 \) and the rest of the parameters are the same as in Fig. 5. The dotted line in (a) shows the dispersion curve obtained by linearizing about the base state for \( n=0.8 \) and setting \( n=1 \) and \( Bn=0 \) in Eqs. (11) and (12).

In Fig. 6, we investigate the effect of varying \( n \) on the stability characteristics for \( Bn=4 \); the rest of the parameters remain unaltered from Fig. 5. For the larger \( h^0 \) values examined, decreasing the value of \( n \), which reflects an increase in the shear-thinning tendency of the non-Newtonian layer has a stabilizing effect. In contrast, for \( h^0=0.2 \), the opposite trend is seen, although the growth rates appear to be weakly dependent on variations in \( n \) in this case. We have also isolated the effect of power-law behavior on the linear stability through its modification of the base state by linearizing about a base state with \( n=0.8 \) and setting \( n=1 \) and \( Bn=0 \) in Eqs. (11) and (12). A comparison of the results of this analysis, shown by the dotted line in Fig. 6, with the solid line, leads to similar conclusions to those drawn above: the simplified analysis underestimates the maximal growth and cut-off wavenumber.

The effect of varying the density ratio on the dispersion curves is examined in Fig. 7. As can be seen from Fig. 7(a), increasing the value of \( r \) appears to be destabilizing in the range \( 0.1<r<2 \). For the smallest values of \( r \) considered, the low-wavenumber cutoff is associated with a disturbance of intermediate wavenumber rather than \( \alpha=0 \). As \( r \) is increased, the low-wavenumber cut-off and most dangerous modes shift towards \( \alpha=0 \) and the dispersion curves become broader; the high-wavenumber cut-off appears to be relatively insensitive to variations in \( r \) in the range \( 0.1<r<2 \), as shown in Fig. 7(a). A further increase in \( r \), however, leads to a decrease in the maximal growth rate but a shift of the most dangerous and high-wavenumber cut-off modes towards larger wavenumbers, as shown in Fig. 7(b). Although the results shown in Fig. 7 are for \( h^0=0.5 \), similar trends were observed for different \( h^0 \) values (not shown).

The dependence of the stability characteristics on \( r \) can be explained by inspection of the energy “budgets” of the points labelled A, B, and C in Fig. 7, which are listed in Table II. It is seen that the largest contribution to KIN is due to TAN, confirming the most unstable mode to be of the “interfacial” type. It can also be seen that REY1 and REY2 are negative for C, whereas REY2 provides a positive contribution to KIN for points A and B. The corresponding values for the \( Bn=0 \) case are given in brackets in Table II. It is clearly seen that similar trends to those associated with the \( Bn=4 \) case are also observed in the Newtonian case. It appears that the total viscous dissipation is largest at the extreme values of the density ratio examined and this may provide an explanation for the nonmonotonic dependence on \( r \) shown in Fig. 7.

FIG. 7. Effect of varying the density ratio \( r \) on the dispersion curves for small, (a), and large, (b), \( r \). The rest of the parameters are \( Bn=4 \), \( n=1 \), \( Re=100 \), \( n=10 \), \( h^0=0.5 \), \( G=0 \), and \( \Gamma=1 \). The labels A, B, and C are used to designate global maxima in the dispersion curves associated with \( r=0.1, 2, 100 \), respectively; the energy “budgets” associated with these points are provided in Table II.
The effect of varying $h^0$, $m$, and $\Gamma$ in the presence of a finite yield stress is investigated next. As can be seen from Fig. 8(a), in which we show the dependence of the growth rate associated with the most dangerous mode, $\omega_i$, on $h^0$, increasing the value of $h^0$ has a nonmonotonic effect on $\omega_i$; there exists an intermediate value for $h^0$ for which $\omega_i$ is maximized. The dependence of $\omega_i$ on $m$ is similarly nonmonotonic, as demonstrated in Fig. 8(b). The presence of a yield stress amplifies the nonmonotonic trends already present in the Newtonian case, which are also shown in Fig. 8, particularly for variations in $h^0$. We have also found that increasing the relative significance of the interfacial tension effects to be stabilizing monotonically (not shown); an increase in $\Gamma$ decreases the value of the wavenumber associated with the cut-off mode, as expected.

We have also explored the effect of increasing Re on the stability characteristics in the presence of non-Newtonian rheology. We show in Fig. 9 the parametric dependence of the dispersion curves on Re for $Bn=0$ and $Bn=12$. Panel (a), which depicts the curves associated with the “interfacial” mode, demonstrates the destabilizing influence of inertia; increasing Re leads to an increase in the maximal growth rate, and increasing $Bn$ reinforces this trend and further destabilizes the flow. We have carried out an energy decomposition for the Re=100 and Re=1000 cases, the results of which are shown in Table III. Inspection of these results reveals that the increase in TAN for $Bn=0$ is counterbalanced by a substantial increase in viscous dissipation; furthermore, in the case of Re=1000 and $Bn=0$ there appears to be a substantial decrease in TEN, which is stabilizing. These effects conspire to widen the interval of “unstable” wavenumbers for $Bn>0$.

In panel (b), we show dispersion curves generated by plotting the imaginary part of the second leading eigenvalue against $\alpha$ for the same parameters as in (a). These curves are therefore associated with another mode, distinct from the “interfacial” mode. This mode, which will be shown below to be of the “shear” type, has a band of $\alpha$ for which $\omega_i>0$ at Re=2000. Hence, at sufficiently large Re, there are two unstable modes. In the following section, we shall focus attention on the least stable of the two, the “shear” mode.

### B. Shear mode

Here, we consider Re $\in [10^4; 5 \times 10^4]$ and find another unstable mode in addition to the “interfacial” mode. The neutral stability curves of the second unstable mode for different Bingham numbers are shown in Figs. 10(a) and 10(b). It is seen that the presence of a finite yield stress is destabilizing for $h^0=0.5$ and stabilizing for $h^0=0.2$. We see that in the former case this coincides with the unstable waves being shorter than in the Newtonian case. These trends are also evident upon inspection of the dispersion curves shown in Fig. 11, which furthermore demonstrate that increasing $Bn$ has a stabilizing influence on the “interfacial” mode for $h^0=0.2$ and $h^0=0.5$. Here, it is also seen that the second mode is considerably less unstable than the “interfacial” modes even at large Re and mode competition is not an issue here. In spite of this large disparity in growth rate, these unstable modes can still be observed experimentally since their dimensional growth rate is not excessively small; their effect on the stability of the flow cannot therefore be neglected.

In order to investigate this behavior in more detail, we compute the energy budgets of the most dangerous modes, labelled A–D in Fig. 11; these are listed in Table IV. Inspection of Table IV reveals that, for both $h^0=0.5$ and $h^0=0.2$, the largest positive contribution to the spatially averaged rate of change of disturbance kinetic energy is due to the Reynolds stresses in the upper fluid. This indicates that the second unstable mode corresponds to a “shear” mode. In Fig.
FIG. 9. Effect of varying the Reynolds number, Re, on the dispersion curves generated by plotting the imaginary parts of the two leading eigenvalues against $\alpha$ with $Bn=0$ (dashed lines) and $Bn=12$ (solid lines). The rest of the parameters are $n=1$, $m=10$, $r=1$, $h^0=0.5$, $G=0$, and $\Gamma=1$.

FIG. 10. The effect of varying $Bn$ on the neutral stability curves of the “shear” mode; (a) $h^0=0.5$ and (b) $h^0=0.2$. The rest of the parameters are $n=1$, $m=10$, $r=1$, $G=0$, and $\Gamma=1$.

FIG. 11. Effect of varying $Bn$ on the dispersion curves with Re=30 000; (a) $h^0=0.5$ and (b) $h^0=0.2$. The rest of the parameters are the same as in Fig. 10. The curves associated with the “shear” modes are shown in the insets of panels (a) and (b).

FIG. 12. The cross-stream structure of the real and imaginary parts of $\psi$ associated with the most dangerous “interfacial” and “shear” modes in Fig. 11(a) shown in (a) and (b), respectively.

FIG. 13. The effect of varying the flow index, \( n \), on the neutral stability curve of the “shear” mode; (a) \( h^2=0.5 \) and (b) \( h^2=0.2 \). The rest of the parameters are \( r=1, Bn=4, m=10, G=0, \) and \( \Gamma =1 \). The dotted line in (a) was obtained by linearizing about a base state with \( n=0.8 \) and \( Bn=4 \) and by setting \( n=1 \) and \( Bn=0 \) in Eqs. (11) and (12).

FIG. 14. The effect of varying \( n \) on the dispersion curves with \( Re =50 \,000 \); (a) \( h^2=0.5 \) and (b) \( h^2=0.2 \). The rest of the parameters are the same as Fig. 13.

FIG. 15. The effect of varying \( m \) on the neutral stability curves of the “shear” mode; (a) \( h=0.5 \) and (b) \( h=0.2 \). The rest of the parameters are \( n=1, Bn=4, r=1, G=0, \) and \( \Gamma =1 \).

FIG. 16. The effect of varying \( r \) on the neutral stability curves of the “shear” mode; (a) \( h=0.5 \) and (b) \( h=0.2 \). The rest of the parameters are \( n=1, Bn=4, m=10, G=0, \) and \( \Gamma =1 \).
12, we also show the cross-stream structure of $\psi$, which contrasts the shape of the stream function associated with the most dangerous "interfacial" mode and the second unstable, "shear" mode, in Fig. 11(a).

We have verified that for cases wherein the viscosity of the lower fluid is less than that of the upper fluid, the shear mode is associated with the lower fluid (evidence of three unstable shear modes was only found in preliminary results at Reynolds number values that are beyond the scope of this study). It is also evident from Fig. 11 and Table IV that an increase in $Bn$ for $h^0=0.5$ is destabilizing despite a concomitant decrease in REY$_2$; this is due to a decrease in total viscous dissipation and in the stabilizing contribution of REY$_1$. For $h^0=0.2$, the stability characteristics appear to be weakly dependent on variations in $Bn$.

In Figs. 13 and 14, we show the effect of varying the flow index $n$ on the neutral stability and dispersion curves of the "shear" mode. It is seen that increasing $n$ is destabilizing for both $h^0=0.2$ and $h^0=0.5$; this effect becomes more pronounced with increasing $h^0$. This can also be understood by examining the energy budgets of the modes labelled A–D in Fig. 14 that are listed in Table V; increasing $n$ for $h^0=0.5$ leads to a decrease in the total viscous dissipation and the stabilizing contribution from REY$_1$, which counterbalances the large decrease in REY$_2$; this leads to an overall destabilizing effect. We also show in Fig. 13(a) that linearizing about a base state associated with $n=0.8$ and $Bn=4$ and setting $n=1$ and $Bn=0$ in Eqs. (11) and (12) underestimates the critical Re.

We have also investigated the effect of $m$ and $r$ on the neutral stability curves of the "shear" mode in the presence of a yield stress. As shown in Figs. 15 and 16, increasing $m$ and decreasing $r$ is destabilizing, leading to lower threshold Re values. These trends are insensitive to changes in $h^0$. The nonmonotonic dependence on $r$ associated with the "interfacial" mode (see Fig. 7) is absent in the case of the "shear" mode.

IV. CONCLUSIONS

We have investigated the linear stability of two-layer pressure-driven flow in a channel. We have considered the case in which the upper layer is Newtonian while the lower one is non-Newtonian, whose rheological behavior is described by a Herschel-Bulkley model. This model incorporates the effects of finite yield stress as well as power-law behavior. In order to examine the stability characteristics of the flow, we have derived an Orr-Sommerfeld eigenvalue problem, which features a pair of coupled fourth-order, ordinary differential eigenvalue equations for the stream functions in both layers; here, the eigenvalue corresponds to the wave speed. These equations are parameterized by a Bingham number, $Bn$, and a flow index, $n$, which characterize the relative significance of the yield stress and power-law properties of the non-Newtonian fluid, respectively, in addition to viscosity, density and thickness ratios, and gravitational and interfacial tension parameters. The Orr-Sommerfeld problem was solved using a perturbation technique valid for low wavenumbers and numerically using a spectral collocation for arbitrary wavenumbers; only two-dimensional perturbations were considered. Comparisons of our numerical predictions with those of our asymptotic analysis and with published results yielded excellent agreement.

Our results indicate that increasing the values of $Bn$ and $n$, which reflect the relative significance of yield stress and power-law behavior, respectively, promote instability when the total dimensionless flow rate of the two fluids is kept constant. The effect of these parameters becomes particularly pronounced at relatively large values of the non-Newtonian layer thickness. At small and moderate values of the Reynolds number, a single unstable mode is found; a second mode becomes unstable at large values of Re. An energy balance shows that the former is an "interfacial" mode, whereas the latter corresponds to a "shear" mode associated with the least viscous fluid. In all cases studied, the growth rate of the "interfacial" mode was found to greatly exceed that of the "shear" mode. This indicates that the former would be the most likely to be observed experimentally although one cannot rule out the possibility that the latter may also be observed since its growth is not vanishingly small. It is important to note that the results could only partly be explained by an analysis based on Newtonian fluids wherein the change in the base-state velocity profile is accounted for. Hence the full non-Newtonian analysis is required for an accurate solution of the stability problem.

APPENDIX: ENERGY BALANCE

We provide here a concise derivation of the energy equation, extending the balance derived by Boomkamp and Miesen (see also references therein), amongst others, to the non-Newtonian system studied in the present paper. Decomposition of this equation into energy production and dissipation terms allows one to isolate the mechanisms by which energy is transferred from the base flow to the disturbances. This decomposition also allows one to determine the type of instability mode, whether "interfacial" or "shear.

The energy equation is derived by taking the inner product of the horizontal and vertical components of the Navier-Stokes equations with their respective velocity components. The resultant equation is then averaged over the wavelength, $\lambda$, and integrated over the height of channel. Application of this procedure to the equations in both fluids, addition of the resultant equations, and making use of the Gauss-divergence theorem yields

$$\sum_{j=1}^{2} \text{KIN}_j = \sum_{j=1}^{2} \text{DIS}_j + \sum_{j=1}^{2} \text{REY}_j + \text{INT}, \tag{A1}$$

where subscript $j=1$ and $j=2$ represent the lower (non-Newtonian) and upper (Newtonian) fluids, respectively. In Eq. (A1), KIN$_j$, DIS$_j$, and REY$_j$ are expressed by
KIN\(_j\) = \frac{r_j}{\lambda} \int_0^{\rho_j} dy \int_0^\lambda dx \left[ \frac{1}{2} \left( \frac{\partial u_j^2}{\partial x} + \frac{\partial v_j^2}{\partial y} \right) \right], \quad (A2)

DIS\(_j\) = - \frac{1}{\lambda \text{Re}} \int_0^{\rho_j} dy \int_0^\lambda \mu_j dx \left[ 2 \left( \frac{\partial u_j}{\partial x} + \frac{\partial v_j}{\partial y} \right) \right] + 2 \left( \frac{\partial j}{\partial y} \right)^2, \quad (A3)

REY\(_j\) = \frac{r_j}{\lambda} \int_0^{\rho_j} dy \int_0^\lambda dx \left[ - \frac{\partial \phi_j}{\partial y} \frac{\partial U_j}{\partial y} \right], \quad (A4)

for the lower fluid, \(\mu_1=\eta_1^{m-1}+Bn_1\), \(r_1=r\), \(a_1=0\), \(b_1=h\), and for the upper fluid, \(\mu_2=1\), \(r_2=1\), \(a_2=h\), \(b_2=1\). KIN\(_j\) represents the spatially averaged rate of change of disturbance kinetic energy and is proportional to the growth rate. DIS\(_j\) represents the viscous dissipation of energy and is always negative; note the presence of the non-Newtonian fluid. INT=\(\text{NOR}+\text{TAN}\) is associated with the existence of an interface and is decomposed into NOR and TAN, the work done by the velocity and stress disturbances in the directions normal and tangential to the interface, respectively. NOR is given by

\[
\text{NOR} = \frac{1}{\lambda \text{Re}} \int_0^{\rho_j} \left( \partial_1 \tau_1^{xy} - \partial_2 \tau_2^{xy} \right) a dx, \quad (A5)
\]

which is further decomposed into TEN and HYD, work done against the deformation of the interface due to interfacial tension and gravity, respectively,

\[
\text{NOR} = \text{TEN} + \text{HYD} = \frac{1}{\lambda \text{Re}} \int_0^\lambda \left( \partial_1 \tilde{\eta}_{xx} + \partial_2 \tilde{\eta}_{yy} \right) a dx + \frac{1}{\lambda \text{Re}} \int_0^\lambda \left( \partial G \tilde{\eta} \right)_{yy} a dx. \quad (A6)
\]

TAN, is given by

\[
\text{TAN} = \frac{1}{\lambda \text{Re}} \int_0^\lambda \left( u_1 \tau_1^{xy} - u_2 \tau_2^{xy} \right) a dx. \quad (A7)
\]

In Eqs. (A5) and (A7), the components of the stress tensor are defined as

\[
\tau_{ij}^{xy} = \mu_j \left( \frac{\partial u_i}{\partial y} + \frac{\partial u_j}{\partial x} \right) \quad \text{and} \quad \tau_{ij} = p_j + 2\mu_j \frac{\partial u_j}{\partial y}. \quad (A8)
\]

where \(p_j\) denote the pressure disturbances.
